Commercial Banks and Their Business Loan Portfolio: 
This Recovery and the Future 

by 

Sydney Smith Hicks* 

I. Introduction 

According to many observers this recovery period has been very different from previous recoveries in the sense that business loans at commercial banks have recovered so slowly. Economists worry about the strength of business loans because they indicate the strength of business spending. The stronger business spending, the stronger will be our recovery. Generally, bankers were mystified by the lack of strength in business loans in 1975 and the continued recovery weakness of business loans at the large banks. No doubt banks over these last few years have maintained relatively more liquid portfolios than they otherwise would have done, due to this expectation of a rebound in business borrowing. 

The existing models of business borrowing generally did not predict the decline in business loans in 1975. A better forecast of business borrowing would have enabled bankers to improve profitability by enabling them to make more accurate portfolio decisions. The model presented here and estimated through 1974, forecasts the decline in 1975 and tracks the current period fairly well. 

In order to assess the cause of this weakness in business borrowing a simple demand and supply model for the business loan market

* Financial Economist, Federal Reserve Bank of Dallas. A preliminary version of this paper was presented at the Financial Management Association Annual Meetings, Minneapolis, Minnesota, October 12-14, 1978. The author would like to thank Karen J. Harmeyer for her efficient and accurate research assistance throughout this study.
is examined after prior studies of business loan behavior are discussed in Section II. Based upon this model, equations for the change in business borrowing at large commercial banks and for the change in business borrowing from small commercial banks are estimated and discussed in Section IV through VI. Major results of this study are that (1) large bank and small bank markets are structurally dissimilar, and (2) superior forecasts for total business loans can be achieved by forecasting from large and small bank equations.

II. Previous Studies of Business Loan Behavior

Prior studies of business loan behavior generally fall into two categories: demand studies or demand and supply studies. Four recent studies—those by Harris [5], Goldfeld [4], Hendershott [6], and the FMP model [10]—are summarized on Table 1. Many studies of business loan behavior mention very little, if any, theoretical justification for the inclusion of certain explanatory variables. Thus, what is notable about the four lists of demand explanatory variables is their diversity. When there is general agreement that the variable should be included, there is lack of agreement about whether or not the variable should enter in level or first difference form. The FMP model includes the level of inventories; Hendershott and Harris include them in first difference form. When the lagged business loan variable is included, it is in level form in Goldfeld's study, in first difference form in Hendershott's study, but is in combination with another variable in the FMP formulation.

In the case of the interest rate variable in the demand specifications, the disagreement is more complex. First, there is relatively
Table 1
Previous Studies' Explanatory Variables for the Change in Business Loans

### Demand Studies

**Harris (1976)**
- ΔBook value of business inventories *
- ΔBusiness fixed investment
- Δ(Prime rate—commercial paper rate)
- ΔCash flow

**Goldfeld (1969)**
- Business loans lagged one period
- Prime rate
- Treasury bill rate
- Quarterly dividend payments
- Business sales
- Time deposits lagged one period

### Demand and Supply Studies

**Hendershott Model (1968)**
- Demand
  - ΔBook value of business inventories
  - ΔCommercial loan rate
  - ΔBusiness loans lagged one period
- Supply (variables determining Δ commercial loan rate)
  - Corporate Aaa rate
  - Monetary base
  - ΔBusiness loans lagged one period
  - Commercial loan rate lagged one period

**FMP Model (1969)**
- Demand
  - Business inventories
  - Inventory adjustment factor
  - Expenditures on producers' durables
  - Expenditures on non-residential structures
  - GNP minus total investment (current and lagged)
  - (Treasury bill rate — commercial loan rate) (ΔTotal business product)
  - (Corporate Aaa rate — commercial loan rate) (ΔTotal business product)
  - (Amount of total investment adjusted for the inventory valuation adjustment — ΔBusiness loans), lagged one period
- Supply (variables determining commercial loan rate)
  - Commercial and industrial loans/demand plus time deposits
  - Corporate bond rate
  - ΔFederal Reserve discount rate
  - Commercial paper rate, current and lagged one through five periods

* The symbol Δ stands for "change in".
l little agreement regarding which rate or rates should be included. The second issue is whether the chosen rate should enter in level form, first difference form, or in deviation from another rate. And thirdly, one of the models converts the interest rate variable into dollar terms, whereas the other models use percentage terms.

The supply specifications contained in the Hendershott and FMP models also display diversity. The only variable upon which both models agree is that the corporate long-term bond rate should be included. It is the only interest rate in Hendershott's formulation, whereas the FMP model includes three different interest rates. The quantity constraint variable is the monetary base in Hendershott's model and is the ratio of business loans to the sum of demand and time deposits in the FMP model.

In 1976, Harris reestimated Goldfeld and Hendershott's models. With these reestimations of Goldfeld and Hendershott, his own model, and simulations of the FMP model, Harris generated forecasts of 1975 business loan behavior. The Goldfeld, Hendershott, and FMP models underpredicted the 1975 decline by $24 billion, $7 billion, and $8 billion with root-mean-square-errors of 6.56, 2.35, and 2.41, respectively. Harris overpredicted the decline by $.5 billion with a root-mean-square-error of 1.09. With the data base used in this study, the Harris model was reestimated and forecasts for 1975 were generated. The reestimated Harris

\[ r-m-s-e = \sqrt{\left(\frac{\sum e_i^2}{n}\right)} \]

where \( e_i \) is the error, or actual less predicted, in each period.
model still overpredicts the decline in 1975, but by an increased average error of $3.4$ billion and a root-mean-square-error of $1.64$.

Only the Harris model captured the extraordinary loan weakness in 1975. Harris' major conclusion about this period was that business loans were weak because of the lack in strength of inventory spending and because there was an exceptional recovery in business cash flows. Inventory spending and cash flows are demand variables. Supply variables played no role in Harris' model and thus were not causative factors.

III. The Business Loan Market

In order to understand the business loan market, an examination of the portfolios of the participants is necessary. Although commercial banks and nonfinancial businesses have very complex balance sheets, only simple representations are used as the basis for this study. Table 2 contains a concise summary of the model as well as an abbreviation key.

Nonfinancial business firms can be characterized as financing positions in cash (CSH), inventories (INV), and/or fixed capital (CAP) by means of loans from commercial banks (BL), other liabilities which can be short or long term (OL) and net worth (NW). The balance sheet constraint for these firms is (Table 2, Equation 4)

$$NW_F = CSH_F + INV + CAP - BL - OL.$$  
Assume that at a given point in time the amounts of fixed capital (CAP) and inventories (INV) the firm has are known to it, as well as the volume of retained earnings or net worth ($NW_F$). Given these three quantities, the level of bank loans demanded by the business firms ($BL^d$) depends upon the interest rate charged by banks (the prime rate, $r_p$) and the interest rates
Table 2

A Simple Model of Business Loan Determination

Model

1. \( BL^d = d(p_1, r_{cp}, r_{Aaa}, INV, CAP, NW_F, BL_{t-1}); d_1, d_6 < 0 \)

2. \( BL^s = s(p_2, r_T, RAM, TLI, BL_{t-1}); s_2, s_3 < 0 \)

3. \( BL^d = BL^s = BL \)

4. \( NW_F = CSH_F + INV + CAP - BL \)

5. \( NW_B = CSH_B + R + L + I - DL \)

6. \( \Delta CAP = BFI \)

7. \( \Delta NW_F = CF \)

Model Solution for BL

Level Form:

8. \( BL = f(p_3, r_{Aaa}, r_T, RAM, TLI, INV, CAP, NW, BL_{t-1}) \)

First Difference Form:

9. \( \Delta BL = g(\Delta r_{cp}, \Delta r_{Aaa}, \Delta r_T, \Delta RAM, \Delta TLI, \Delta INV, BFI, CF, \Delta BL_{t-1}, \text{Constant}) \)

Model Key

- BFI: Business fixed investment
- CAP: Capital
- CF: Cash flow
- CSH_F: Commercial bank cash
- CSH_B: Nonfinancial business cash
- DL: Deposit liabilities
- I: Securities
- INV: Inventory investments
- L: Total Loans
- NW_B: Commercial bank net worth
- NW_F: Nonfinancial business net worth
- OL: Other Liabilities
- RAM: Reserve Adjustment Magnitude
- \( r_{Aaa} \): Corporate Aaa rate
- \( r_p \): Prime rate
- \( r_T \): Treasury 3- to 6- month bill rate
- TLI: Total loans and investments, \( L + I \)
on other short- and long-term liabilities firms can issue (the commercial paper rate, \( r_{cp} \), and the long-term bond rate, \( r_{Aaa} \)).

The quantity of business loans demanded from banks varies inversely with the prime rate. However, the demand for business loans varies positively with interest rates on other types of liabilities, the level of business inventories and the level of fixed capital. It varies negatively with net worth.

It is possible that business firms do not adjust their bank loans completely to equilibrium values within one period. This partial adjustment may be the result of incomplete information and transactions costs. As a result, some portion of the volume of loans desired but not undertaken in the current period will be undertaken in the next period. Consequently, the past level of loans \( [BL_{t-1}] \) positively affects the demand function for loans in the current period. Another reason for including this variable is the bank-customer relationship. Business firms may borrow more today, other factors being equal, in order to assure themselves of future loan availability. Consequently, current loan demand depends on expected future loan levels. Furthermore, if future loan levels are a function of the past loan level, then \( BL_{t-1} \) is an explanatory variable in the demand equation.

---

2/ The level of cash holds by the firms is determined as a residual once the other factors on the balance sheet are known.

3/ The bank-customer relationship was introduced to the literature by Donald R. Hodgman [9]. It has been extensively discussed and tested by J. H. Wood [12].
Turning to the banking sector, banks can be characterized as financing positions in cash \( (CSH_B) \), reserves \( (R) \), loans \( (L) \), and securities \( (I) \) by means of deposit liabilities \( (DL) \) and net worth \( (NW_B) \). The balance sheet constraint for the commercial banks is (Table 2, Equation 5)

\[
NW_B = CSH_B + R + L + I - DL.
\]

In the current time period, bankers decide how many deposit liabilities and then set interest rates on those deposits to attract the funds. After subtracting required reserves \( (R) \) from the deposit liabilities \( (DL) \) and adding to that result the current amount of net worth \( (NW_B) \), the banks are assumed to allocate their "disposable assets" between securities \( (I) \) and loans \( (L) \) based on alternative rates of return on each.\(^1\) If the volume of excess reserves is small for the whole system, then the "disposable assets" (or the portfolio constraint variable) can be measured either as the sum of deposit liabilities plus net worth less reserves or as total loans and securities. The second approach is followed here, and thus the abbreviation for the portfolio constraint variable is TLI. An increase in the size of this portfolio constraint variable will increase holdings of both loans and securities.

Given the portfolio constraint variable, the amount of funds allocated by commercial banks to business loans is determined by what the banks can charge on the loans (the prime rate,

\(^1\) "Disposable Assets" is a term used by William C. Brainard and James Tobin [2]. Brainard and Tobin make allowances for possible differences in the effect of time deposits and demand deposits on loan supply in their theoretical model. This complication is ignored here. The volume of cash is determined once all the other magnitudes are known; thus, the balance sheet constraint is satisfied.
and what the banks could earn on security investments (represented by the Treasury bill interest rate, \( r_T \)). When the prime rate increases and other factors remain the same, banks will increase the quantity of business loans supplied. When the Treasury bill rate increases, banks will decrease the supply of business loans because of the more attractive return on alternative investments.

The banks' allocation of total earning assets between business loans and other investments also depends on bank liquidity, which is affected to some extent by reserve requirements. For example, a bank facing a 5-percent reserve requirement would hold 5 cents in required reserves against $1 of deposits; if the $1 deposit was withdrawn, the bank would have to liquidate 95 cents of earning assets. A bank with a 15-percent reserve requirement would hold 15 cents in required reserves and would need to liquidate only 85 cents of such assets. Thus, when reserve requirements are low, it behooves the banker to be invested more heavily in securities than loans because of the relative liquidity of securities. The higher the reserve requirement, the less need there is for liquidity and the greater loans should be relative to securities.

A variable used previously in studies of the money supply process to measure the effects on reserves of changes in required reserves is the reserve adjustment magnitude, or RAM. The reserve adjustment

5/ RAM is discussed in detail by Leonall C. Andersen and Jerry L. Jordan [1] and by Albert E. Burger and Robert H. Rasche [3]. RAM was originally calculated so that a comprehensive variable could be constructed to measure the total impact of Federal Reserve policy on the monetary aggregates. The monetary base, which includes RAM, would then reflect the extent of open market operation, borrowing at the discount window, and reserve requirement changes.
magnitudes translates changes in reserve requirements relative to a base period into dollars of reserves freed up or absorbed. An increase in reserve requirements reduces RAM and, thus, should lead to an increase in business loans relative to securities because the total earning asset portfolio can be less liquid. 6/

Finally, the lagged level of business loans \( (BL_{t-1}) \) may affect the current level of business loans supplied by banks. Banks may not instantaneously adjust to desired levels the business loans they supply. This may be the case if, for example, information is incomplete and there are transactions costs in adjusting. The presumption is made that some portion of any desired increase in the supply of business loans not accomplished today will be undertaken in the next period. Consequently, the relation between last period's loan levels and today's loan levels is positive.

The quantity of business loans at any point in time is such that the amount supplied equals the amount demanded. This quantity is obtained from the simultaneous solution of Equations (1) through (3), which yields Equation (6). Model Equation (6) cannot be estimated as it is because there are no accurate measures of the fixed capital stock \( (CAP) \) or the net worth \( (NW) \) of nonfinancial businesses. However, business fixed investment \( (BFI) \) measures the addition to capital stock each period, and an indication of the addition to net worth each

---

6/ In a simplified model, \( \text{RAM}_t = (r - r_t) D_{t-2} \), where \( r \) is the required reserve ratio in the base period, \( r_t \) is the required reserve ratio in the current period, and \( D_{t-2} \) is the level of deposits two periods ago. Because the model for business loans is estimated in first-difference form, the first difference of RAM is used in the estimated model. The change in RAM captures the dollar amount of reserves freed or absorbed by concurrent changes in reserve requirements, adjusted for shifts in deposits among banks.
period is undistributed corporate profits (CF). As a result, the equation was estimated in first-difference form, as represented in Equation (7).

To the extent that a bank responds to an increase in business loan demand by selling more liabilities, a portion of the portfolio constraint variable becomes endogenous. If this were true for all banks, we could not be sure whether an increase in the aggregate portfolio constraint variable led to an increase in business loans or vice versa. However, deposit liabilities and, thus, total earning assets for the whole banking system are importantly constrained by the total amount of reserve money supplied by the Federal Reserve System. That the assumption of an exogenous portfolio constraint variable (ATLI) is a reasonable assumption has been confirmed by the two-stage least-squares estimates. The two-stage estimates attribute at least as much importance to the supply effects of total earning assets as do ordinary least-squares estimates.

IV. Estimation of the Model

The model's equation for the change in business loans was estimated for all commercial banks, for large commercial banks (the

---

7/ The CF variable is undistributed corporate profits plus the inventory valuation adjustment and depreciation. There exists the possibility of measurement error in the business loan series due to judgments regarding loan classification. Consequently, a constant should be and was added for econometric reasons. For a discussion of these problems, see Robert S. Pindyck and Daniel L. Rubinfeld [12, pp. 128-129].

8/ The problem of simultaneous-equation bias in the ordinary least-squares estimation used here would remain if the Federal Reserve tended to supply or withdraw reserves automatically in response to variations in bank loan demand. Since the Trading Desk of the Federal Reserve follows an interest rate target between the monthly meetings of the Federal Open Market Committee, this could be a problem for data covering relatively short periods. But over the quarterly intervals used in this study there is often substantial movement in short-term interest rates, so total earning assets of banks can still be considered exogenous.

2/ Hicks [8, pp. 15-16].
weekly reporting banks), and for small commercial banks (all banks excluding the weekly reporting banks). [Table 3] The equations were estimated from 1960III-1974IV; 1960III represents the beginning of the period for which bank data disaggregated by size is available and 1974IV is the last data point before the seemingly unusual business loan behavior began. All of the regressions are significant (as measured by the F statistic), and the Durbin-Watson statistics (D-W) are close to 2.0 indicating very little residual autocorrelation.

Before discussing the estimated coefficients it is worthwhile to examine whether or not disaggregation of the business loan equations is appropriate. To find out, another regression was estimated based on a test developed by Zellner.10 In general functional form the change in business loans at all banks can be explained as follows:

\[
\Delta BLA = f(C, \Delta r_{cp}, \Delta r_{Aaa}, \Delta r_{T}, \Delta RAM, \Delta TLIA, \Delta INV, \Delta F, \Delta BLA_{t-1}, \Delta TLIL, \Delta BLL_{t-1}).
\]

Two variables from the large bank equation, \(\Delta TLIL\), and \(\Delta BLL_{t-1}\), were added to the aggregate model equation of Table 3. If the estimated coefficients on these variables are significantly different from zero, then disaggregation is appropriate. The equation was estimated over the period 1960III-1974IV. The coefficient of \(\Delta TLIL\) was positive with a t-statistic of 1.14, and the coefficient of \(\Delta BLL_{t-1}\) was positive with a t-statistic of 4.24. The \(R^2\) was .9216 (with an adjusted \(R^2\) of .9029). An F-test conducted on the hypothesis that both coefficients equaled zero resulted in the rejection of the hypothesis.

To test the stability of this result, the equation was estimated over sample periods extended by one year at a time. The

significance of $\Delta BLL_{t-1}$ fell while the significance of $\Delta TLIL$ grew.

In summary, disaggregation of the aggregate business loan market yields more information than the aggregate equation for business loan behavior.

V. A Comparison of Large and Small Bank Business Loan Markets

A few interesting differences and similarities between small and large bank business loan markets can be noted by comparing the coefficient estimates in Table 3. Generally, the coefficient estimates have the positive or negative signs economists would expect, given the prior behavioral assumptions. Despite a great degree of collinearity among the variables (which reduces t-statistics), many of the explanatory variables are still significant.

At the large banks, for example, an increase in the commercial paper rate ($\Delta r_{cp}$) of one percentage point will increase business loans by $1.232$ billion (as the alternative means of financing becomes more expensive). If the reserve requirements are lowered releasing $1$ billion in reserves, business loans increase $0.72$ billion. If either inventories ($\Delta INV$) or total loans and investments ($\Delta TLIL$) increase by $1$ billion, business loans increase by $0.34$ and $0.18$ billion, respectively. Despite the view of some large banks that their business loans increase when business fixed investment ($BFI$) rises, these results do not indicate this.11/ Contrary to Harris' study, these results do not indicate a significant impact of cash flows on the change in business loans. And finally, the combined lagged adjustment of large banks and their customers results in

11/ See Herman [7].
a significantly positive lagged effect of last period's change in business loans on this period's change in business loans. A $1 billion increase in business loans last period will increase this period's business loans by about one quarter of a billion dollars.

The results for small banks are similar with respect to sign, but the magnitudes of the coefficients are much different. Multicollinearity among the interest rates (two short-term and one long-term) appears to be more of a problem in the small bank equation estimates; none of the interest rates have coefficients significantly different from zero. As with large banks, a billion dollar increase in either inventories or total loans and investments increases business loans significantly by $0.07 billion or $0.05 billion, respectively. A rather surprising result is the negative coefficient on RAM; in other words, when reserve requirements are lowered thus releasing reserves and increasing RAM, the change in business loans is reduced. There is some comfort in the fact that the coefficient is not significant at the 95-percent level. Unlike the large bank regression, (1) rising levels of business fixed investment add to the current change in business loans, (2) increasing cash flows measurably depress borrowing at small banks (the t level is more negative, but still not significant) and (3) the lagged effect of the past period's change in business loans does not significantly affect the current change in business loans.

The lagged change in business loans coefficient can be interpreted as a measure of the importance of the loan-customer relationship in the small and large bank markets. The insignificant coefficient on ABLS_{t-1} does make sense if it is true that in the small bank markets firms do not have much choice as to where to bank, and
the banks do not have much competition. In the large bank market, there may be relatively more competition among bankers and more of the large bank customers may have alternative financing options; as a result, the loan-customer relationship may become more significant as a tool for maintaining the banks' market shares.\textsuperscript{12/}

VI. Forecasting Business Loans

Besides the fact that multicollinearity among many of the explanatory variables did mean that some coefficients were unexpectedly insignificant (for example, the cash flow variable), collinearity causes the estimates of the coefficients to change dramatically when sample periods are updated and when data is revised. One or more variables could be eliminated to reduce collinearity; this would also reduce the number of variables which would have to be forecast before a business loan prediction could be generated. However, eliminating variables does result in specification error. To warrant confidence in the coefficient estimates and the predictions based on them, any specification that omits variables should predict outside the sample period at least as well as the whole model. Otherwise, the specification error introduced would be too costly for the gain in coefficient stability.

In fact, some of the specifications of the model that omitted some interest rate and/or RAM variables did predict 1975 better than the whole model estimated through 1974 IV, as judged by the root-

\textsuperscript{12/} The insignificant coefficient on the lagged change in small bank business loans remained robust for sample period endpoints ranging from 1970-1977I. When the 1977II-1978I data was added, the coefficient became significant and positive. Because the small bank equation is unstable in this period, more data is needed before this new result can be viewed as accurate.
mean-square-error statistic. From the alternative specifications of
the model estimated with data available in March 1978, the following
specifications for large and small banks (which subsequently will be
called the restricted model equations) minimized the r-m-s-e for 1975:

(a) \( \Delta BLL = f'(C, \Delta r_{Aaa}, \Delta r_{T}, ATLIL, AINV, BFI, CF, \Delta BLL_{t-1}) \)

and

(b) \( \Delta BLS = g'(C, \Delta r_{Aaa}, \Delta r_{T}, ARAM, ATLIS, AINV, BFI, CF, \Delta BLS_{t-1}) \). \(^{12/}\)

The equation for large banks (a) excludes \( \Delta RAM \) and \( \Delta r_{cp} \) from the theo-
retical model; only \( \Delta r_{cp} \) is removed from the small bank equation (b).

Tables 4 and 5 contain the root-mean-square-errors of various predic-
tion periods for the theoretical model and the restricted model, re-
spectively.

No matter what specification was examined, a superior total
forecast for 1975 was always made by forecasting the small and large
bank components and then adding them together. For example, this result
may be observed from the first line of Table 4. When the theoretical
model was estimated over estimation periods ending later than 1974IV,
the predictions for total business loans made from the disaggregated
small and large bank equations were generally better than aggregate
predictions. The aggregate predictions were substantially better than
disaggregated predictions only during periods when the structural

\(^{12/}\) The coefficient estimates are presented in Hicks [8]. The \( \Delta r_{Baa} \)
variable was used instead of \( \Delta r_{Aaa} \) in the small bank regressions
because \( \Delta r_{Baa} \) probably proxies the long-term borrowing costs of
small bank customers better than \( \Delta r_{Aaa} \). However, because of the
statistical tests conducted on the model in this paper, it was
necessary to use \( \Delta r_{Aaa} \) instead of the \( \Delta r_{Baa} \) variable.

equations were unstable and thus could not be considered reliable.14/

There appear to be some sizable gains in prediction accuracy for large bank business loans when the restricted model is used, regardless of the period of estimation and forecast period. This does not seem to be true for the small banks prediction errors; the r-m-s-e statistics are very similar. Although the errors are generally lower for the small bank predictions, they are 58 and 60 percent of the average quarterly change in small bank business loans during 1975 for the theoretical and restricted models, respectively. The large bank predictions are 75 and 40 percent of the average change in large bank business loans in 1975 for the theoretical and restricted models, respectively.

The total business loan root-mean-square-error statistics improve dramatically from $2.56 billion for the aggregate bank theoretical model in 1975, to $1.48 billion for the restricted disaggregate predictions. The lowest r-m-s-e statistic for 1975 generated from prior studies was 1.64; the worst was 6.56. While the restricted model does a better job predicting total business loans, the error does remain 89 percent of the 1975 average quarterly change in business loans.

The model does predict the decline in total business loans in 1975 better than prior models.15/ (Chart 1) Most of the weakness occurred at the large banks, while changes in small bank business loans remained stable. In 1976 and 1977 large bank predictions were good in the sense of not missing consistently in the same direction. On the other hand, the changes in small bank business loans in 1977 were consistently

underestimated. Structural stability tests presented elsewhere indicate relatively more structural instability in the current time period for the small bank business loan market than for the large bank market.16/

VII. Conclusion

In the case of the business loan market, aggregation of small and large bank markets is not appropriate. Estimates of the disaggregated large and small bank business loan equations provide interesting similarities as well as dissimilarities. One of the most interesting results is that last quarter's change in business loans in the small bank market provides no significant information about today's change in business loans, contrary to the results for the large bank business loan market.

Understanding business loan behavior has proven to be a very difficult task. Recognizing the structural diversity between large and small markets rather dramatically increases the explanatory and predictive power of the model. Modeling both the demand and supply sides of the market yielded equations which, upon estimation, provided better predictions of 1975 than alternative formulations. Estimated through 1974, the model predicts the decline in total business loans, as well as the relative weakness in the large bank loan market. To the extent the model increases the ability of bankers to predict business loan behavior, bankers will be able to improve profitability by making more accurate portfolio decisions.
